Article published on 23 June 2011

The unprecedented outbreak of Shiga toxin/verotoxin-producing *Escherichia coli* (STEC/VTEC) O104:H4 in Germany in May and June 2011 displayed several novel epidemiological, microbiological and clinical features. Infection with STEC/VTEC, also referred to as enterohaemorrhagic *E. coli* (EHEC), with or without haemorrhagic uraemic syndrome (HUS), which is usually a disease of pre-school children and equally distributed among the sexes, affected in the current outbreak mostly women over the age of 20 years (87%). In addition, several intriguing microbiological characteristics of the new epidemic strain have just been published [1,2].

With regard to the clinical characteristics, STEC/VTEC O104:H4 again differed remarkably from previously described STEC/VTEC infections. During a telephone conference on 9 June, organised by the European Centre for Disease Prevention and Control (ECDC) with clinical experts and nephrologists from 16 Member States of the European Union (EU) and several European and national professional societies, German colleagues shared their first clinical experiences from their patients. Severe infection with STEC/VTEC O104:H4 usually presented as a disease in three phases. On admission, about 80% of the patients suffered from bloody diarrhoea and 20% from watery diarrhoea. In 25% of the cases with bloody diarrhoea, signs of HUS (based on laboratory parameters of haemolysis, thrombocytopenia, and renal function tests) evolved after 3–5 days [3]. Completely unexpected, however, was the observation that severe neurological symptoms developed after about 3–10 days in roughly 50% of patients with HUS, even though clinical and laboratory markers of HUS were improving. These patients who had at first seemed to improve or respond to therapy, deteriorated again. Some patients even had to be re-hospitalised 3–4 days after they had been discharged. Neurologists were very concerned about the severity of neurological symptoms, ranging from mild disorientation and cognitive dissociation to stupor or severe, life-threatening seizures. Despite the impressive clinical presentation, routine neuroradiological examination revealed only mild alterations, if any. Worryingly, especially patients with seizures seemed to respond only weakly to standard antibody-based treatment regimes.

In this issue of *Eurosurveillance*, Cordesmeyer et al. [4] report about an unusual case of STEC/VTEC O104:H4 infection associated with colonic ischemia, and Kuijper et al. [5] describe a case of household transmission of STEC O104:H4 from a mother to her child. In both cases, neurological symptoms were present, with severe manifestation and as yet unclear neurological outcome in the child. From a public health perspective, these and other rather unusual clinical presentations and sequelae of STEC/VTEC O104:H4 infections are of importance when it comes to supporting and guiding the identification of STEC/VTEC cases, providing recommendations for the follow-up of patients, or adapting existing case definitions for the disease. In order to share and disseminate relevant clinical data among European clinicians and to foster the dialogue between clinicians and epidemiologists, a clinical support initiative was established by the ECDC as a reaction to the outbreak. Nominated clinical contact points, and up to two additional clinical STEC/VTEC experts per EU Member State were invited by the ECDC to join this initiative. It comprises a password-protected internet discussion forum for timely exchange of information, expertise and best practices. In addition, an audio podcast (available through the ECDC website) has been produced, in which a clinical expert from Germany describes his experiences with the presentation, treatment, and outcome of patients infected with STEC/VTEC O104:H4.

This clinical support initiative is one more component of the European response against this devastating outbreak and the possible future establishment and spread of the new STEC/VTEC O104:H4 strain in Europe. It will add to and support the ECDCs ongoing efforts in the field of scientific advice, outbreak response and surveillance.

Acknowledgments

The clinical support initiative of ECDC is represented by Marc Struelens, Anna-Pelagia Magiorakos, Sybille Rehmet, Susanne Freudenberg, and Andreas Jansen.

Article published on 23 June 2011

An increasing rate of infections with Shiga toxin/verotoxin-producing Escherichia coli (STEC/VTEC) O104:H4 has been observed in Germany since May 2011, with unusually high numbers of patients suffering from haemolytic uraemic syndrome (HUS). We report a STEC/VTEC O104:H4 case without HUS, presenting with colonic ischaemia demanding surgery. This atypical clinical presentation of STEC O104:H4 infection might indicate new severe complications associated with this uncommon strain, and highlights the importance of immediate interdisciplinary assessment of STEC/VTEC patients.

Clinical presentation and initial evaluation

A woman in her 80s presented to our Emergency Department on 1 June with increasing abdominal pain and a history of nausea, primarily associated with dysuria that had been lasting for five days. On 29 May, the day after the onset of those symptoms, non-bloody diarrhoea had followed. The initial physical examination showed a mildly distended abdomen with diffuse pain and left upper quadrant tenderness without rebound. Blood tests showed a massive elevation of white blood cell count (29,300/µl; normal range: 4,300–10,000/µl) as well as an elevation of both C-reactive protein (32.42 mg/dl; normal range: ‹0.5 mg/dl) and lactate (2.5 mmol/l; normal range: 0.5–2.4 mmol/l). Ultrasound and computed tomography (CT) scans of the abdomen revealed distinctive amounts of ascites and wall thickening of parts of the transverse and descending colon, but did not show any disturbance of the main arteries and veins. Considering pseudomembranous colitis as a differential diagnosis, we decided to perform a colonoscopy.

The endoscopy showed a normal rectum and sigmoid colon, macroscopically. The descending colon had a circularly swollen, partly pale, partly bluish mucosa, with no evidence of bleeding after biopsy, a combination of symptoms highly suspicious of ischaemia (Figure 1).

Surgical intervention

Following the confirmation of ischaemia by endoscopy of the descending colon on 1 June, surgery was performed immediately. Non-occlusive ischaemia of the descending colon with gangrenous bowel wall was detected during the operation, with patent macroperfusion of the medial colic artery and inferior mesenteric artery arcade, as well as the left colic artery up to the

Figure 1

STEC/VTEC: Shiga toxin/verotoxin-producing *Escherichia coli*.

gangrenous bowel wall. Therefore, a left hemicolectomy was performed, followed by thorough abdominal irrigation.

Pathology

Pathological examination of the removed part of the colon revealed wall thickening up to 1 cm and extensive necrosis throughout the entire intestinal wall with fibrinous-purulent exudation. The border area showed vital mucosa with erosive and phlegmonous inflammation, membranous-like fibrin exudation and crypt destruction, consistent with an ischaemic origin (Figures 2 and 3).

Postoperative course

After the operation, which occurred late in the evening on 1 June, the patient was admitted to the intensive care unit. The next morning, as a precautionary measure, due to the ongoing Shiga toxin/verotoxin-producing Escherichia coli (STEC/VTEC) O104:H4 outbreak in Germany, the patient was placed in isolation and a stool sample was sent for further evaluation. The second day after surgery, seven days after the onset of the initial abdominal symptoms, neurological impairments were observed in terms of decelerated reactions of the patient, lack of orientation and intermittent response when addressed. Clinical examination was uneventful for abdominal, respiratory and haemodynamic findings. Laboratory studies were not suspicious for haemolytic uraemic syndrome (HUS): creatinine, elevated up to 1.7 mg/dl at admission (normal range: ‹1.2 mg/dl), had immediately revealed decreasing tendencies (0.8 mg/dl at day four) after intravenous fluid application, and was therefore most likely due to diarrhoea-induced hypovolemia. Lactate dehydrogenase (LDH) ranged between 139 U/l (normal range: 135-225 U/l) at admission and 318 U/l six days after, whereas platelets always presented within normal limits. The patient was monitored closely and improved neurologically during the next day. During the following 48 hours, however, noticeable neurological deficiencies with disturbance of vigilance, aphasia and apraxia were observed, as well as myoclonia of the extremities. Seizures did not occur. PCR analysis of the stool samples confirmed Shiga toxin 2-producing *E. coli* consistent with the strain responsible for the current outbreak, O104:H4, on 6 June. Monitoring the patient for an onset of HUS continued but has not eventuated as of 21 June.

Discussion

The ongoing outbreak of infections with STEC/VTEC, also commonly referred to as enterohaemorrhagic *E. coli* (EHEC), in Germany is one of the largest worldwide [1]. Besides causing non-bloody and bloody diarrhoea, the STEC/VTEC subtypes may also lead to HUS, a severe complication that is characterised by thrombocytopenia, microangiopathic haemolytic anaemia, and decreased renal function. So far, *E. coli* O157:H7 had been described as the predominant serotype causing HUS in approximately 10% of all cases to date [2,3], whereas the strain responsible for the current outbreak, which has been identified as *E. coli* O104:H4, is an extremely rare strain, hardly described during the last decade [4]. With adults and predominantly women being infected, the age and sex distribution in the ongoing outbreak is unusual, but might be related to gender-specific differences in dietary habits: vegetables, which are generally more often consumed by women, are still suspected to have been contaminated and at the source of this outbreak. In addition, an unusually high number of patients have developed HUS: The latest data account for 814 patients with HUS from a total of 3,587 infected patients in Germany [1]. Neurological complications, which were seen, on average, in about 25% of HUS patients in former outbreaks [2], could also be more severe in this outbreak. Indeed,

the exchange among German clinicians, who set up a web-based platform to communicate clinical information in the context of the current outbreak, indicates higher numbers, but this has not been systematically evaluated so far. Taken together, the various aspects of the ongoing outbreak may suggest an increased virulent potential of the identified strain.

Besides HUS, STEC/VTEC-associated bowel ischaemia, as an additional severe complication, is rarely described in the literature. Very few reports of colonic necrosis and perforation due to Shiga toxin-induced intestinal damage exist, and in all these reports, this type of complication affected *E. coli* O157:H7-infected individuals. This complication was moreover mostly encountered in paediatric patients with concomitant HUS [3]. Only one case of ischaemic colitis in a non-HUS adult has been previously described [5].

Conclusion

Besides leading to its major complication HUS, infection with STEC/VTEC O104:H4 can also cause neurological complications and atypically present as bowel ischaemia, as shown in our patient. Since ischaemia-induced colonic wall thickening is difficult to differentiate from pseudomembranous colitis in CT imaging, endoscopy is essential and should be considered at an early diagnostic stage. Notably, our patient has not shown any signs of HUS to date, but obviously, even unexpected complications have to be considered as a differential diagnosis in STEC/VTEC O104:H4 infected patients, calling for interdisciplinary diagnostic investigations.

Article published on 23 June 2011

Following the outbreak of haemolytic uraemic syndrome (HUS) and haemorrhagic colitis in Germany, two patients returning from a stay in Germany developed HUS due to *Escherichia coli* O104:H4 in the Netherlands. The index case developed symptoms eight days, and her child 15 days after their return. It is very likely that transmission resulted from secondary spread from mother to child. Recommendations should be made to prevent secondary transmission within households.

Introduction

Since early May 2011 one of the largest ever reported outbreaks of haemolytic uraemic syndrome (HUS) and bloody diarrhoea caused by Shiga toxin/verotoxin-producing *Escherichia coli* (STEC/VTEC), also referred to as enterohaemorrhagic *E. coli* (EHEC) has affected Germany [1]. The outbreak strain was identified as an enteroaggregative Shiga toxin-producing *E. coli* O104: H4 (EAggEC) [2]. Initial findings suggested raw vegetables and salads as vehicle of infections and recommendations were made to abstain from these products. Epidemiological investigations implicated an organic sprout farm in Lower Saxony near Hamburg as the potential source of the outbreak [3]. On 10 June 2011, German public health and food safety authorities issued a joint statement recommending people to abstain from consuming sprouts. A decrease in the number of new cases was seen after 6 June [4].

We describe here two cases of HUS and hemorrhagic colitis that occurred in the Netherlands and were associated with the outbreak in Germany.

Case descriptions

Patient A

On 24 May, a woman in her 30s was admitted to a hospital in the Netherlands with bloody diarrhoea and abdominal pain of two days. Common bacterial gastroenteritis was considered and no antibiotic treatment was initiated. Four days after admission, blood examination revealed severe HUS. The patient was transferred to the Leiden University Medical Centre (LUMC) for haemodialysis which eventually proved not to be necessary.

A tentative diagnosis of HUS due to Stx1-negative, Stx-2 positive, extended spectrum beta-lactamase (ESBL)-producing *E. coli* was confirmed by culture on sorbitol MacConkey agar of a stool sample collected two days after admission to the first hospital. Further identification of *E. coli* serotype O104 was performed at the Dutch National Institute for Public Health and the Environment (RIVM). A real-time PCR for Stx2 directly in stool sample was also positive [5]. Stool samples on admission to LUMC were already negative in culture and real-time PCR. Since 30 May 2011, the patient has gradually been recovering from HUS.

Patient A had travelled to Northern Germany for two days in May 2011, accompanied by six relatives, among them her 10 month-old child.

Patient B

The 10-month-old child of Patient A was examined first on 29 May 2011, one day after transfer of the mother to the LUMC. At the time, the child had mild diarrhoea free of blood, and blood examination did not reveal any abnormality. A stool sample was collected and tested positive for Stx2 in the real-time PCR. Culture revealed growth of ESBL-positive *E. coli* O104. On 30 May, the child developed fever and blood abnormalities compatible with HUS, and was admitted to hospital. The next day, it developed neurological symptoms, i.e. seizures, and was transferred to a specialised child dialysis centre, where experimental treatment with eculizumab was started. The patient received prolonged mechanical ventilation and inotropic therapy. Three weeks after transfer, the patient is still on dialysis and the neurological outcome is unsure.

Family members

Of the other five relatives of Patients A and B who had also travelled to Northern Germany, one developed mild diarrhoea 16 days after their return, but microbiological examinations were not performed since the diarrhoea resolved one day later and no HUS developed. The remaining relatives did not develop any symptoms and were not investigated for the presence of *E. coli* O104.

Microbiological and public health implications

HUS is a rare disease in the Netherlands, with approximately 20 patients per year [6]. During the outbreak in Germany, 854 cases of HUS and 2,848 non-HUS STEC/VTEC cases have been reported as of 22 June, of which 4.6% and 2.2%, respectively, were found in other Member States of the European Union [7]. In the Netherlands, four HUS (including Patients A and B described here) and five non-HUS laboratory-confirmed STEC/VTEC cases were detected. All acquired the infection during a recent visit to Germany.

Microbiological examination of stool samples from Patient A gave negative results in the real-time PCR and culture at the time of transfer to another hospital when HUS had fully developed, six days after disease onset, indicating the need to apply diagnostic tests early in the disease. Similarly, Patient B had positive faeces tests and excreted the organism before haemorrhagic colitis and HUS developed.

We hypothesise that Patient B probably acquired HUS by secondary transmission within the household, because the child developed illness only 15 days after return form Northern Germany. The child had spent much time with her mother during her stay at the first hospital, when the mother developed diarrhoea. Before admission of the child to LUMC, the mother had not been advised to take any specific hygienic measures. The child was not breastfed at the time. The age of the child makes it unlikely that it had eaten a food product such as sprouts.

Recently, a group of investigators reported that the strain causing the outbreak in Germany is in fact not a typical virulent Shiga toxin-producing *Escherichia coli* strain, but instead is a more rare, hybrid pathotype that harbours the phage encoded the Shiga toxin gene in an EAggEC background [2]. These findings are relevant for understanding the epidemiology since EAggEC is a common pathogen causing diarrhoea in travellers and persistent diarrhoea in infants and young children living in countries with poor sanitation. In contrast to STEC/VTEC strains, which that have an animal reservoir, mostly ruminants, EAggEC strains probably have a human reservoir only.

Secondary transmission frequently occurs in outbreaks caused by classical EHEC O157. A review of 90 confirmed outbreaks in the United Kingdom, Ireland, Scandinavia, Canada, the United States and Japan revealed that approximately 20% of all outbreak cases were the result of secondary spread [8]. Interestingly, the spread was significantly influenced by age and modes of transmission. A lower median age of the index patients was associated with a higher rate of secondary cases and household contacts aged one to four years were most likely to become infected. Immediate separation of a paediatric patient from its siblings when there is a clinical suspicion of STEC/VTEC O157 infection has been suggested as an important measure in the prevention of secondary cases [9]. Isolation of all symptomatic primary patients immediately after they receive a microbiological diagnosis of STEC/VTEC O157 infection could potentially decrease the number of secondary household cases by 50% [9]. In this family however, the primary case patient was an adult. Since young children usually have extensive close contacts with their parents; separation of young children from a parent with a suspected STEC/VTEC or *E. coli* O104 infection should be considered in order to prevent secondary transmission to the child.

Article published on 23 June 2011

We present the findings of a six-year surveillance period (2005–2010) of human West Nile virus (WNV) infection in Tel Aviv district, Israel. Initial notifications of positively identified patients received from the Central Virology Laboratory were followed by epidemiological investigations of the local district health office. During 2005–2010, 104 patients, 79 with WNV neuroinvasive and 25 with WNV non-neuroinvasive disease were reported. The median age of the patients with a neuroinvasive disease was 74 years (range: 15 to 95 years) and 53 of such patients had encephalitis, 14 had acute flaccid paralysis, and 12 had meningitis. The case-fatality rate in these patients was 8%. The average annual incidence of neuroinvasive disease during 2005–2010 was 1.08 per 100,000 population. The incidence declined by 86% steadily between 2005 and 2009 (p for trend=0.005), but increased by more than six-fold in 2010. Elderly (≥65 years) men, comprising 25 patients of whom 24 were chronically-ill, had the highest incidence of WNV encephalitis (p<0.001). These findings are concordant with previous data, at the national level, published in Israel and the United States. Notably, the percentage of previously healthy patients, who developed a neuroinvasive disease was the highest (37%, p=0.001) in the surveillance period in 2010.

Introduction

West Nile virus (WNV) is a mosquito-borne arbovirus of the family *Flaviviridae*. Numerous avian species serve as the amplifying hosts. These include, migratory birds, such as the white storks which travel across Israel each autumn, as well as urban species, such as the common house sparrows. Transmission to humans mainly occurs by mosquito vectors, principally by mosquitoes of the genus *Culex*, during their active period, usually between mid-summer and early autumn. WNV has rapidly expanded in both the eastern and western hemispheres in the past two decades [1,2].

Human West Nile fever, caused by laboratory-confirmed WNV infection, was reported in Israel for the first time in the early 1950s, with several outbreaks in that decade, and an additional outbreak in 1980 [3]. The largest outbreak (439 serologically-confirmed cases with 29 deaths) of human WNV infection in Israel occurred in 2000, with a 73% rate of neuroinvasive disease in hospitalised patients [3,4]. Following this outbreak, a national surveillance system was established for humans and mosquitoes [5] and since 2001 WNV infection is notifiable in Israel. The surveillance system detects new cases of human WNV infections and characterises viral genotypes. The system is based on initial notifications of probable or confirmed cases of WNV infection by the Central Virology Laboratory (CVL) and on the subsequent epidemiological investigations of these patients by the local district health offices.

This report summarises a six-year period (2005–2010) of human WNV surveillance in the Tel Aviv district. This most densely populated urban district of Israel included 7,425 residents per square kilometre at the end of 2009, according to the Israel Central Bureau of Statistics [6].

Methods

Epidemiological investigation

The Tel Aviv District Health Office routinely receives notifications from the CVL about probable or confirmed cases of WNV infection in patients who are residents of the district. The local health office initiates an epidemiological investigation by collecting available information on the patients and by using a standard national-based questionnaire. For hospitalised patients, information is gathered from the patients' hospital records, and by conducting an interview with the patient or with a close family member, in order to obtain information regarding risk factors for WNV infection such as occupation, residence or travel near water bodies, recent exposure to mosquitoes, migratory birds and domestic fowl. For non-hospitalised patients, another source of information, in addition to the patient's interview, is usually the family physician.

The gathered demographic, clinical, laboratory and epidemiological data are reported to the Division of Epidemiology, Ministry of Health, Jerusalem.

Laboratory analysis

During the study period, the CVL used a combination of serology assays comprising in-house synchronised IgM-capture (until August 2007), indirect IgG, and indirect IgG avidity ELISAs [4], and from September 2007, the IgM InBios commercial kit (West Nile Detect IgM Capture ELISA, Seattle, Washington, USA) [7]. Results were interpreted according to the manufacturer's instructions. IgM and IgG tests were conducted simultaneously. The avidity IgG test was performed on single samples with IgM and IgG positive results. Unresolved cases were further tested by virus neutralisation assay [8].

Case definition

The following official national laboratory criteria of WNV infection are used by the CVL to define probable and confirmed cases.

• A confirmed case is defined as having at least one of the following criteria: (i) Serological conversion or at least two-fold increase in ELISA test results of IgM antibodies and/or IgG antibodies levels [4,7] in blood or in cerebrospinal fluid (CSF), in paired samples taken at least seven days apart; (ii) IgM antibodies level higher than IgG antibodies level and also IgG avidity lower than 30% in one blood sample; (iii) At least ten-fold higher optical density (OD) of IgM antibodies in CSF in one sample, compared to a reference cut-off level; (iv) Positive result of West Nile viral RNA in CSF, body fluids or body tissues, by real-time RT-PCR assays detecting WNV lineages 1 and 2 [8-10].

• A probable case is defined as detection of WNV IgM antibodies, without detection of IgG antibodies, in one blood or CSF sample or the lack of increase in IgM antibodies, without the presence of IgG antibodies, between paired samples of blood collected one to seven days apart.

The data in this report were summarised and analysed from the district health office's files of individual patients who had an onset of laboratory-confirmed or probable WNV infection, between 1 January 2005 and 31 December 2010. No clinical criteria were used, in addition to the laboratory criteria, for the case definition.

Clinical criteria

The term 'neuroinvasive disease' as used in our analysis refers to WNV-associated diagnoses of encephalitis, meningoencephalitis, meningitis and acute flaccid paralysis (AFP). The clinical definitions of encephalitis, meningitis and AFP, were adopted from previously described definitions [11]. Patients who have had a combined clinical picture of encephalitis and meningitis, hence, meningoencephalitis, were classified as having encephalitis, as in previous reports [12,13]. Also, any presentation of AFP combined with other illness (i.e. encephalitis) was classified as AFP only [12].

We assumed that in non-neuroinvasive patients, there would be a high level of cohort incompleteness due to lack of serological testing and therefore, lack of WNV diagnosis. These patients largely present with a mild nonspecific illness, which is often not followed by seeking medical care [14]. Thus, this report mainly analyses the cohort of WNV neuroinvasive disease patients who usually require diagnosis and treatment within a hospital setting, and therefore, this cohort is more likely to be complete.

Patients were also classified as to whether they had a pre-existing chronic medical condition, which was further classified as to whether it was an immunocompromised state. Any chronic medical condition, excluding psychiatric conditions, was included.

We abstracted these data, post hoc, at the information summary stage of the study from written medical diagnoses in patients' hospital records, where available.

Statistical analysis

For the purpose of p value calculations, we used the exact two-tailed Mann-Whitney U test in case of mean age differences, and not the Student's t-test, because of the small sample size. For the same reason, we used two-tailed Fisher's exact test in case of categorical data and Spearman's rank correlation coefficient for the trend of incidence. Also, the chi-square test with Yates' correction was used for testing differences in the average annual incidence between certain subgroups. A two-tailed p value inferior to 0.05 was considered significant. Statistical analyses were performed using SPSS version 15.0 software (Chicago, Illinois, USA).

The annual average population estimates for the years 2005–2009, used as denominators for incidence calculations, were taken from the Israel Central Bureau of Statistics. The annual average population estimate for 2010 was based on an estimated annual population growth rate of 1.725%, which was derived from the average population growth rate during 2005–2009.

Results

Between 1 January 2005 and 31 December 2010, 104 confirmed or probable cases of WNV infection were reported in the Tel Aviv district. Of these 104 cases, 94 (90%) had an onset of illness in the period from July to the end of October (Figure 1). Eighteen of the 23 (78%) neuroinvasive and non-neuroinvasive cases in 2010, and 18 of the 25 (72%) cases in 2005, occurred in July and August, compared to the occurrence of only 16 of the 56 (29%) cases in the years 2006–2009 combined during the same period.

Seventy-nine patients have had a neuroinvasive disease (Table), all of whom were hospitalised: 53 (67%) had encephalitis, 12 (15%) had meningitis and 14 (18%)

had AFP, of whom two patients had Guillain–Barré syndrome. The median age of all patients with a neuroinvasive disease was 74 years (range: 15 to 95 years) and 51 (65%) of these patients were aged 65 years or older. Fourty (51%) of these patients were males.

Of 79 patients with neuroinvasive disease, 25 (32%) were elderly men (≥65 years), of whom 24 were chronically-ill. Similarly, 26 (33%) elderly women including 25 chronically-ill were part of the 79 patients presenting with neuroinvasive disease.

Patients with encephalitis had a significantly higher mean age than patients with meningitis and AFP (74 years; 95% confidence interval (CI): 70–78 years vs 59 years; 95% CI: 51–67 years, p=0.02). The mean age of patients with meningitis was significantly lower than the mean age of patients with encephalitis and AFP (47 years; 95% CI: 35–60 years vs 73 years; 95% CI: 69–76 years, p<0.001).

Of all 79 patients with a neuroinvasive disease, 69 (87%) had a pre-existing chronic medical condition.

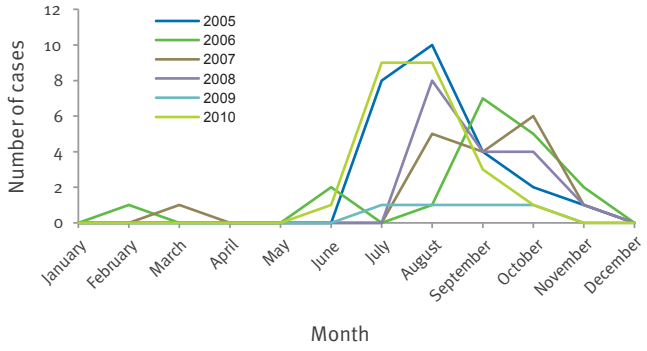
The group of patients with meningitis had a significantly lower percentage of chronic illness when compared to the group of patients with encephalitis (8/12, 67%; 95% CI: 35%-90% vs 49/53, 92%; 95% CI: 82%-98%, respectively, p=0.03). The percentage of patients with a pre-existing chronic medical condition was significantly lower in 2010, when compared to the period between 2005 and 2009 (12/19, 63%; 95% CI: 38%–84% vs 57/60, 95%; 95% CI: 86%–99%, p=0.001).

The case-fatality rate (CFR) of patients with a neuroinvasive disease was six of 79 (8%). The patients who died were older than 74 years of age, five of six were females, five of six had a pre-existing chronic medical condition, and four of six had a diagnosis of WNV encephalitis.

During the surveillance period, the annual percentage of patients with encephalitis, meningitis or AFP ranged between 55% and 90%, 0% and 25%, and, 10% and 33%, respectively (Figure 2).

Figure 1

Human West Nile virus infection confirmed and probable cases, by month of illness onset, 2005–2010, Tel Aviv district, Israel (n=104)



Human West Nile virus infection confirmed and probable cases include 79 cases of neuroinvasive disease and 25 cases of non-neuroinvasive disease.

Deaths (%)	4 (8)	1 (8)	1 (7)	**6 (8)**
Immunocompromised (%)	5 (9)	0 (0)	1 (7)	**6 (8)**
Any chronic medical condition[a] (%)	49 (92)	8 (67)	12 (86)	**69 (87)**

AFP: acute flaccid paralysis.

[a] Most commonly included was a history of one or more illnesses such as essential hypertension, hyperlipidemia, and/or diabetes mellitus.

The average annual incidence of neuroinvasive disease between 2005 and 2010 was 1.08 per 100,000 population (Figure 3). The incidence of neuroinvasive disease declined significantly, between 2005 and 2009, from 1.69 to 0.24 per 100,000 population (an 86% decrease, rs=-0.97, p for trend=0.005), but increased more than six-fold in 2010, to 1.47 per 100,000 population, compared to the previous year. The change in trend, during 2005–2010, of the WNV-associated central nervous system diagnoses (encephalitis and meningitis) was similar to the trend of the WNV-associated peripheral nervous system illness (AFP).

The average annual incidence of neuroinvasive disease, by age, between 2005 and 2010 (Figure 4) demonstrated a peak in incidence among patients aged 75 years or older (7.03 per 100,000 population), while no patients aged less than 15 years were reported. The peak of the average annual incidence of encephalitis and of AFP was in patients aged 75 years or older (5.18 and 1.48 per 100,000 population, respectively) (Figure 5).

The average annual incidence of neuroinvasive disease had a similar pattern among men and women (Figure 6) with the exception that the incidence in male patients aged 65–74 years, was almost three-fold higher than in female patients of the same age group (4.11 per 100,000 population vs 1.41 per 100,000 population, respectively). The latter difference could not be confirmed with statistical significance, but this could be due to the small number of cases in each of the male and female subgroups.

During the surveillance period, elderly men (≥65 years) had the highest average annual incidence of WNV encephalitis in the cohort, and it was significantly higher than the rest of the patients with encephalitis, aged between 35 and 64 years (4.54 per 100,000 population vs 1.19 per 100,000 population, p<0.001).

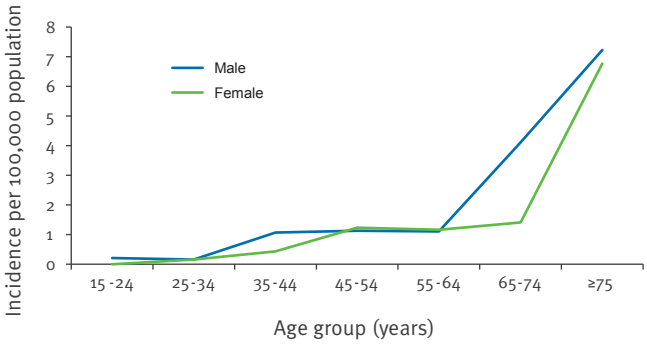
Figure 6

Average annual incidence of human West Nile virus neuroinvasive disease by age group and sex, Tel Aviv district, Israel, 2005–2010



Average annual incidence is calculated using Israel Central Bureau of Statistics average population estimates of Tel Aviv district for 2008.

Similarly, male patients aged 75 years or older had the highest average annual incidence of encephalitis or AFP in the cohort during the surveillance period, which was significantly higher than the rest of the patients, aged between 35 and 74 years, with encephalitis (5.42 per 100,000 population vs 1.46 per 100,000 population, p<0.001) or AFP (1.81 per 100,000 population and 0.33 per 100,000 population, p=0.004). In contrast, female patients aged 75 years or older had the highest average annual incidence of meningitis, but it was not significantly higher than the rest of the patients with meningitis, aged between 15 and 74 years (0.62 per 100,000 population vs 0.17 per 100,000 population, p=0.3).

Discussion

The data that were summarised and analysed in this study reflect a six-year period of WNV surveillance in Tel Aviv district. After several years of successive declines in WNV neuroinvasive disease, its incidence increased sharply in 2010.

We observed, as previously reported by Lindsey et al. [12], a higher incidence of encephalitis in elderly male patients during our surveillance period. These patients were also chronically ill, which may serve as an independent risk factor for WNV neuroinvasive disease [15]. However, five of the six fatalities in the observation period were female patients.

Two-thirds of the patients with a neuroinvasive disease had encephalitis (53/79, 67%), followed by patients with AFP (14/79, 18%). Of those latter 14 patients with AFP, four were diagnosed in 2010 alone. WNV-associated AFP was hardly observed during the large outbreak of 2000 in Israel: 98% of 233 hospitalised patients were diagnosed as having West Nile fever, encephalitis or meningitis but not AFP, which was reported as myelitis by Chowers et al. [13].

In our series, patients with meningitis were significantly younger than patients with other forms of neuroinvasive disease. This age discrepancy was described previously by Lindsey et al. [12].

Our reported CFR for the patients with neuroinvasive disease (6/79, 8%), who were all hospitalised, was similar to the overall CFR in Israel during the outbreak in 2000 (29/439, 7%) [4]. The CFR in our study was however half the CFR of hospitalised patients (33/233, 14%), for whom data were obtained in 2000 [13]. Our reported CFR was also similar to that in the United States (US), which was 9% of the patients with a neuroinvasive disease during 1999–2008, most of whom were hospitalised [12].

Remarkably, the highest percentage of WNV neuroinvasive disease occurring in previously healthy patients was observed in 2010, when compared to the period between 2005 and 2009 (7/19, 37% vs 3/60, 5%, p=0.001).

In our series, meningitis affected patients who were significantly younger on average than patients with other forms of neuroinvasive disease. The year 2010 did not appear to present an exception, although the total number of cases was small (39 years on average (n=3) for patients with meningitis vs 47 years in all years of the surveillance period (n=12)). Because of their younger age, patients with WNV meningitis would be less likely to have underlying medical conditions. Therefore, we examined whether the overall increase of previously healthy patients presenting with WNV neuroinvasive disease in 2010 could have been due to an increase in the number of patients with WNV meningitis in that year; however, of the patients with a neuroinvasive disease in 2010, only three of 19 had meningitis, which was well within the range of annually reported cases of WNV meningitis in the district, between 2005 and 2009 (0/10 in 2007 and 0/3 in 2009 up to 5/20 in 2005).

We also verified if the number of previously healthy patients presenting with a neuroinvasive disease had increased in other years than 2010, such as in 2005, in which a peak in the proportion of meningitis was observed (5/20). There was, however, no lower proportion of chronically-ill patients (17/20) in that year.

Additionally, to our knowledge, there was no change in the surveillance practice over the study time period that could account for the highest percentage of previously healthy patients presenting with WNV neuroinvasive disease observed in 2010.

In the years following the major national outbreak of WNV infection in 2000, various strains of WNV lineage 1 predominated in Israel either in isolated foci or in the entire country [16]. Representative Israeli WNV genomic sequences of viruses isolated from mosquitoes and humans between 2000 and 2009 were deposited in the GenBank/EMBL/DDBJ database under accession numbers GU246634–GU246714 and HM152773–HM152780, respectively.

The emergence of new viral genotypes simultaneously with higher number of human cases was observed in Israel in 2000, 2005, and 2007 [16]. Particularly, in 2005, an increased nationwide WNV activity, with 102 laboratory-confirmed human patients [16] of whom 20% were from the Tel Aviv district, which was a part of the epicentre, was reported [17]. Molecular analysis of human and mosquito isolates revealed a genotype most similar to the one that was isolated in the equine WNV outbreak in Morocco in 2003 [18], and which had not been isolated previously from humans or mosquitoes in Israel [17].

Notably, 2005 and 2010 shared some epidemiological similarities, as we observed in the district: both years had a similar incidence of WNV neuroinvasive disease, higher than the other years of surveillance, including a higher incidence of AFP, which is a long-term

complication of considerable morbidity and mortality [19,20]. In addition, the majority of WNV infection cases in both years had occurred early, already in July and August, compared to later months of occurrence, in the other years.

One possible explanation to the increased incidence of morbidity observed in 2010, which was also accompanied by a higher fraction than before of previously healthy patients could be the recent emergence of another WNV strain or variant, as in 2005. A genotype characterisation of the 2010 WNV strain is however not available to date.

Another explanation for the 2010 epidemiological characteristics could be the early arrival of an extremely hot summer, already in May. This might have contributed to the early peak of WNV season in 2010, in the district. The period of May–July 2010 was warmer than the perennial average of the years 1981–2000 [21-23]. In addition, August 2010 was the warmest measured month in Israel [24,25].

The summer of 2010 was extremely hot also in areas, which usually have a temperate climate, such as northern Greece and Romania. A human WNV outbreak emerged in northern Greece for the first time, early in July 2010 [26]. An additional noticeable outbreak, which also began in early July 2010, was reported in Romania, where a neuroinvasive lineage 2 WNV strain was detected for the first time [27]. Whether there is a possible association between recent climatic extremes in the region, WNV activity, and its mosquito vectors should be extensively studied.

Conclusions

We report on the epidemiological and clinical characteristics of human WNV infection in the Tel Aviv district between 2005 and 2010. As such, it may be limited in time, place and person. Nevertheless, our main body of findings, such as the patients' characteristics, was concordant with previous data, at the national level, published in Israel and the US.

Any successful WNV surveillance system should integrate and maintain both epidemiological and laboratory capabilities for prolonged periods of time, particularly in endemic and densely populated areas, such as the Tel Aviv district.

Article published on 23 June 2011

The prevalence of cytomegalovirus (CMV) infections ranges between 50% and 85% in adults in the United States, and its epidemiology varies in different regions of the world and between socioeconomic and age groups. In Portugal, no study has been carried out to date to determine the prevalence of CMV in the general population. Under the second National Serological Survey conducted in continental Portugal in 2001–2002, we estimated the prevalence of individuals with antibodies to CMV using indirect immunofluorescence to detect virus-specific IgG. The population sample included 2,143 individuals of both sexes and different ages from all 18 districts in Portugal. The national seroprevalence of CMV was determined as 77%. We analysed the proportion of CMV IgG by sex, age group and district of residence. This was the first nationally representative study of seroprevalence of CMV in Portugal. The results of the study indicate that CMV infection is highly prevalent in the population and occurs mainly in the first years of life.

Introduction

Cytomegalovirus (CMV) is a common virus with no known seasonal predominance and with a prevalence that ranges between 50% and 85% of adults in the United States [1-3]. The epidemiology of CMV varies in different regions of the world and in different socioeconomic and age groups [3-5].

CMV establishes a latent state following primary infection, reactivating when there are changes in immune status [6,7]. CMV infections are most often asymptomatic, but when symptomatic, can cause a syndrome similar to clinical and haematological infectious mononucleosis. The virus is excreted through body fluids, and the most common modes of transmission are via the oropharyngeal and genital tract, although transmission can also occur through breast milk, organ transplant or blood transfusions [8-11].

CMV primary infection occurs mostly in childhood and adolescence, but primary infections are also observed in adults [3,11-14]. The infection is important in certain risk groups such as immunocompromised individuals and pregnant women. In immunocompromised individuals, CMV infection is the leading cause of morbidity and mortality, especially in connection with transplants, haemodialysis, cancer, immunosuppressive medication and infection with human immunodeficiency virus (HIV) [8]. Transplacental transmission can occur and primary infection in the first 16 weeks of pregnancy is associated with higher rate of damage in fetal development [15-20]. In primary maternal infection, the probability of transmission of CMV to the fetus is approximately 30% to 40%. In women with CMV reactivation during pregnancy the probability of fetal CMV transmission decreases to approximately 0.5% to 1.4% [21-24]. In developed countries, CMV is a major cause of congenital infection, with an incidence of 0.4% to 2.2% of total live births per year, and is responsible for neonatal morbidity and mortality [19,23,25-27]. The congenital CMV infection is asymptomatic in the neonatal period (the first 28 days of life) in approximately 85% to 90% of infants, but nearly 5% to 15% of these infants show late sequelae during the first years of life, typically hearing deficits and visual impairments [22,28-30]. Approximately 10% to 15% of infants with congenital CMV infection are symptomatic at birth, with manifestations including growth retardation, jaundice, purpura, hepatosplenomegaly, microcephaly, intracerebral calcifications, and retinitis. The risk of long-term neurodevelopmental disabilities is high in these children and include microcephaly, hearing loss, motor deficits, cerebral palsy, mental retardation, seizures, ocular abnormalities and learning disabilities [23,31-34].

In a recent review of priorities for vaccine development, the Institute of Medicine of the National Academy of Sciences in the United States concluded that in terms of healthcare costs and years of life and disability saved, a vaccine against CMV infection should be a priority [35,36].

In Portugal, the prevalence of CMV in the population and the incidence of CMV congenital infection have

not previously been determined. However, in 2003, preliminary results of a prospective study indicated that the proportion of CMV congenital infections was 0.7% in a consecutive population of newborns in the area of Lisbon, as determined using the gold standard technique, shell vial culture of urine [37]. According to a survey by Paixão et al. [38] that screened for CMV congenital infection by PCR of blood samples obtained from Guthrie cards, the proportion of congenital infection by CMV was 1.1% in Portugal and 0.7% in the region of Lisbon in the period from August 2003 to September 2004.

The second National Serological Survey conducted in continental Portugal in 2001–2002 was carried out with two objectives: firstly, to determine the prevalence of individuals with antibodies to vaccine-preventable diseases, as a means of evaluating the national immunisation programme, and secondly, to determine the prevalence of individuals with antibodies to infections deemed important in terms of public health. As part of the second National Serological Survey, we estimated the proportion of individuals with CMV antibodies in Portugal in 2002-2003 in order to assess the prevalence of CMV in the population [39].

Methods

Sampling

The main sample frame that was used to study the immunity to diseases included in the national immunisation programme was calculated to be nationally representative and to adequately cover all age groups, at a sample size of 3,304 individuals of both sexes, homogeneously distributed in eight age groups: 2–4, 5–9, 10–14, 15–19, 20–29, 30–44, 45–64, and ≥65 years. Each age group included individuals from each of the 18 districts of mainland Portugal, to a number proportionally representative for the population of each district. Between 2002 and 2003, the national immunisation programme recruited 3,525 participants at 38 private and public serum collections points, distributed in all 18 districts of mainland Portugal. Individuals were invited to participate until the district and age grids prepared were completed. For the participation of individuals, a fact sheet was prepared with the objectives and benefits of the study and informed consent was obtained either from the participants themselves or from their legal representatives [39].

For our specific study on the prevalence of CMV, we used a sub-sample of 2,143 individuals. Serum samples were taken from the same batch collected during 2002–2003 and analysed in 2003–2004 for the presence of CMV-specific antibodies.

Serological analyses

IgG antibodies specific for CMV were detected by indirect immunofluorescence, using commercial reagents (Merifluor CMV IgG, US) according to the manufacturer's instructions. Samples were added to a layer of human fibroblasts fixed on glass slides on which approximately 10% of cells are infected with CMV strain AD169, and the formation of antigen-antibody complex is viewed using a fluorescent dye. Uninfected fibroblasts on the same slide were used as an internal control of the specificity of the test. The tests were validated with negative and positive control sera. The use of reference sera ensured the reproducibility of results between batches. According to the manufacturer, the test has 97% sensitivity, 100% specificity, 100% predictive value of a positive test and 99% predictive value of a negative test.

Statistical analysis

Statistical analysis consisted in the determination of absolute and relative frequencies (percentages). Binomial confidence intervals were calculated using the exact method that uses the relationship between the F and Binomial distributions attributed to Bliss and Brownlee as described by Zar [40].

Table

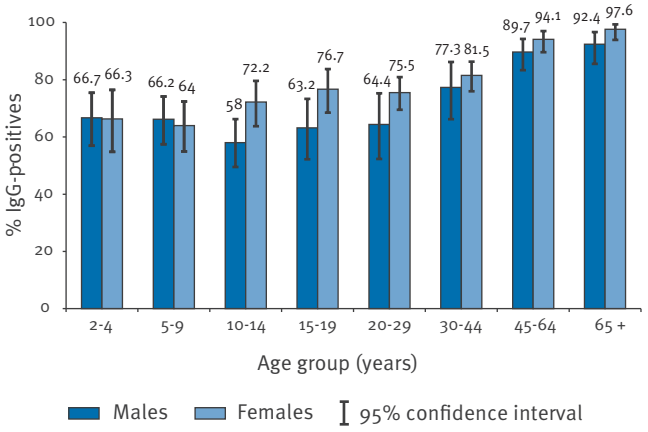
Individuals IgG-positive for cytomegalovirus, by sex, Portugal, 2002-2003 (n=2,143)

Sex	Study participants n	CMV-positive n (%)	95% confidence interval
Male	860	622 (72.3)	69.2–75.3
Female	1,283	1,029 (80.2)	77.9–82.4
Total	**2,143**	**1,651 (77%)**	**75.2–78.8**

CMV: cytomegalovirus.

Figure 1

Percentage of individuals IgG-positive results for cytomegalovirus, by age and sex, Portugal, 2002-2003 (n=2,143)



IgG: Immunoglobulin G.

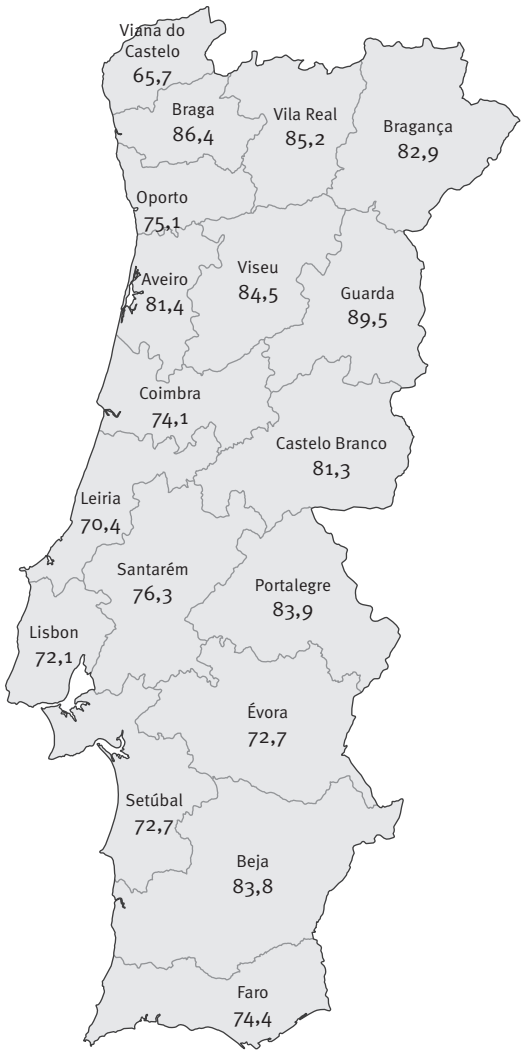
Results

In a total of 2,143 individuals, 1,651 had IgG antibodies to CMV (77%, 95% confidence interval (CI): 75.2–78.8) and 492 were seronegative (23%, 95%: CI 21.2–24.8). Among the male participants, 622 (72.3%) were CMV-positives and among the female participants 1,029 (80.2%) were CMV-positives (Table).

When analysing the distribution of CMV IgG-positive individuals by age, 66.5% of children in the youngest age group (2–4 years) were shown to have antibodies. The percentage of seropositive individuals was similar in age group of 5-9 year-olds and 10-14 year-olds with 65.1% and 64.9%, respectively, and then increased with age, reaching 71.3% in the age group of 15–19 year-olds, 80.5% in the 30–44 year-olds and 95.6% in the oldest group (≥65 years). The percentage of males and females with CMV IgG in each age group is shown in Figure 1.

Figure 2

Proportion of individuals IgG-positive for cytomegalovirus, by district of residence, Portugal, 2002-2003 (n=2,143)



IgG: Immunoglobulin G.

Analysis of the distribution of CMV IgG-positive individuals by district of residence showed that only one of the 18 districts of Portugal, Viana do Castelo, had a prevalence of less than 70% of seropositive individuals. The highest prevalence of CMV-positive residents was found in the districts of Guarda, Braga and Vila Real, with 89.5%, 86.4% and 85.2%, respectively (Figure 2).

Discussion

In Portugal, the second National Serological Survey has established, for the first time, the prevalence of individuals with CMV-specific IgG. The results of this study indicated that CMV infection was highly prevalent in the population (77%), similar to what has been described for other countries, and that it occurred predominantly in the first years of life [1,3,41-46].

Seroprevalence for CMV between the age of two and four years was high, with 66.5% of IgG-positive children in this age group (95% CI: 59.3–73.2). Children younger than two years were not included in the study and conclusions on the situation at that age can therefore not be drawn. However, breastfeeding is known to be a significant source of CMV transmission to children and plays an important role in the epidemiology of CMV infection as CMV is reactivated during lactation in nearly every seropositive mother [47-49]. The proportion of infants who acquire CMV during the first year of life is directly related to the prevalence of maternal infection and to the proportion of mothers who breastfeed. In countries where breastfeeding is widely practiced and most mothers are seropositive, for example in south and south-eastern Europe, regions of Asia, Africa and Latin America, more than 50% of infants acquire CMV within the first year of life [8,50]. The seroprevalence found in the age group between two and four years (66.5%) was probably the result not only of transmission via breastmilk but also of oral transmission from other children and from seropositive adults they are in close contact with when they start attending day care centers at that age [51,52]. This was similar to the seroprevalence of 53.8% found in several studies performed in children of that age in Brazil (region of São Paulo) [53]. It was higher than that in Italy (region of Parma, 28% at two years of age) and Finland (41% at eight years of age) and lower than in Venezuela (region of Valencia; 83.3% between two and four years of age) and Turkey (region of Antalya, 82.1% in children between one and six years of age) [41,54-56].

The antibody prevalence in children at school age (age groups 5–9 years and 10–14 years) was similar to that at pre-school age, but increased further to 71.3% (95% CI: 64.8–77.2) in the age group between 15 and 19 years, which corresponds to a greater sexual exposure, in addition to close non-sexual contact [3,8,13,57]. The antibody prevalence in this age group was identical to that in the 20–29 year-olds. Studies with similar age groups conducted in other countries, such as the United States, Japan, France, England, Poland and Russia, describe seroprevalences ranging between 51.5% and 78.0% [3,44,58-62].

The prevalence of individuals with CMV IgG gradually increased further in the three oldest age groups, with values of 80.5% (95% CI: 75.6%–84.8%), 92.2% (95% CI: 88.7%–94.9%) and 95.6% (95% CI: 92.4%–97.7%), suggesting that sexual transmission was an important route of transmission of the virus in the population [8,63,64]. Another recognised source of adult CMV infection are children. Children infected with CMV shed virus in saliva and urine for years, providing an opportunity for continued spread to other children and susceptible adults (close relatives and day care workers) [8,51,65–67].

IgG-positivity was equally common in both sexes in the age groups of 2–4 and 5–9 year-olds, while in the older age groups, females were more likely to be IgG-positive than males. The statistically significant difference of 8% between males and females in the prevalence of individuals with CMV IgG could be explained by the fact that women may have more contact with children. This horizontal mode of transmission presents a risk to mothers, pregnant women and those with occupations associated with exposure to children, such as teachers and day care providers [23,63,68,69].

Nevertheless, it should be noted that in our study, 24.5% and 18.5% of women of reproductive age (from 20 to 29 years and 30 to 44 years, respectively) were susceptible to CMV, which led us to conclude that there is a considerable risk for congenital infection due to maternal primary CMV infection, which leads to fetal infection in approximately 40% of cases [11,16].

Possible approaches to preventing congenital CMV infections include improved hygiene behaviour of seronegative pregnant women, administration of CMV hyperimmune globulin (HIG) to pregnant women with primary infection, and vaccines, once available, administered to girls or women before pregnancy [70].

Several studies have been done to determine whether changing protective behaviour prevents child-to-mother transmission of CMV during pregnancy [71-74]. The United States Centers for Disease Control and Prevention recommend that seronegative pregnant women assume that children are secreting CMV in their urine or saliva. They advise on simple hygiene such as frequent hand washing, wearing gloves for specific childcare tasks and avoiding intimate contact with their child such as sharing utensils, food or towels, and kissing on or near the mouth [75-77].

Despite advances in the diagnosis of maternal-fetal CMV infection and approaches to prevent congenital CMV, an effective prenatal therapy is unavailable. A prospective, non-randomised study of pregnant women who acquired CMV infection during pregnancy and who received passive immunisation with CMV HIG, showed that this therapy was associated with a significantly reduced risk of congenital CMV disease and infection and had no adverse effects [70,78,79]. Recent case reports supported safe administration of oral ganciclovir to mothers of CMV-infected fetuses, with no teratogenic side effects when given in the early stages of pregnancy [70,80,81]. The efficacy of ganciclovir still remains to be defined in controlled trials. Other early experience with treatment of intrauterine CMV infection using maternal oral administration of valaciclovir showed that it decreased the viral load in fetal blood significantly and could potentially also reduce the morbidity of prolonged intrauterine infection [82]. The absence of adverse effects or teratogenecity of valaciclovir is compatible with its clinical use, but a well-designed randomised controlled trial is needed.

Currently, there is no approved vaccine for CMV, but two vaccines are in phase II studies: one is a recombinant vaccine containing the major envelope glycoprotein B of the virus with the adjuvant MF59 (gB/MF59) that induces high levels of neutralising antibodies, is safe and immunogenic in adults and infants, preventing also maternal CMV infection [36,83]. The other vaccine is the live attenuated CMV Towne strain that stimulates neutralising antibodies comparable to those induced by wild type virus and protects renal transplant patients from severe CMV after transplantation [78,84].

The main interventions for the prevention of CMV infection should be aimed at women who wish to become pregnant, women who care for children and immunocompromised individuals. These individuals in whom exposure to CMV can be most detrimental will be the target groups for possible administration of a future vaccine.

Acknowledgements:

The project 'Evaluation of National Vaccination Programme and improving their cost-effectiveness' is responsibility of the Directorate General of Health and was funded by Health XXI Programme, under the III Community Support Framework. The planning of the protocol, the fieldwork and analysis of data were done by technicians of the National Observatory of Health (currently the Department of Epidemiology) in the National Institute of Health. Monitoring and review of all phases of the project was the responsibility of a group of experts in the clinical, laboratory and epidemiologic area.
